Exact Reachability Analysis for Planning Skew-Line Needle Arrangements for Automated Brachytherapy

Animesh Garg1, Timmy Siauw2, Guang Yang1, Sachin Patil3, J. Adam M. Cunha2, I-Chow Hsu2, Jean Pouliot2, Alper Atamturk1, Ken Goldberg1,3

Abstract—When planning skew-line needle arrangements for automated brachytherapy, one objective is to identify a set of candidate needles that enter from a specified entry region, avoid specified organs-at-risk and sufficiently cover the target (tumor) volume. Existing methods use uniform or random sampling to generate a set of candidate needles, which may not adequately cover the target volume. In this paper we present an exact reachability analysis that can be used to guide the selection of candidate needles and to identify which subset of the target volume may not be reachable. Assuming linear needles, a polyhedral entry zone, organs at risk modeled as the union of convex polyhedra, and a polyhedral target volume, we give an exact polynomial time algorithm for checking existence and calculation of the non-reachable set in the target volume. We perform experiments using patient data from 18 brachytherapy cases and found that 11 cases had non-empty occluded volume ranging from 0.01% to 4.3% of target volume. We also report a sensitivity study showing the change in the occluded volume with dilation of the avoidance volume and entry region.

I. INTRODUCTION

The need to compute exact visibility in the presence of obstacles appears in many computer graphics and computational geometry problems. This study explores a non-traditional application of this body of work for a cancer therapy called brachytherapy, which is a form of radiation therapy where the radioactive source is placed in proximity to the tumor. Prostate cancer has a high incidence among men, accounting for 14.4% of all cancers diagnosed and 5.1% of all cancer deaths [1]. brachytherapy is a common and successful treatment modality for prostate cancer. In prostate brachytherapy, the radioactive source is delivered to the tumor site using an arrangement of temporarily inserted needles. Currently, this needle arrangement is restricted to only parallel needles by a needle guide, which allows little freedom to avoid puncturing healthy organs and can lead to trauma and side effects.

Inserting needle arrangements made up of skew-lines (i.e. non-parallel, non-intersecting lines) can address some of the limitations of parallel needle guides. Previous work developed Needle Planning by Integer Program (NPIP) [2].

Fig. 1: This figure shows a target volume (blue), avoidance volume (cyan), and entry zone (black). In the context of prostate brachytherapy, a radiation therapy for prostate cancer, these structures model the prostate (blue), penile bulb (cyan), and perineum (black), respectively. This study develops an exact algorithm for finding an occluded volume (red), which is the subset of the target volume that cannot be reached by any straight line originating in the entry zone that does not intersect the avoidance volume, or showing that no such volume exists. This algorithm could be an important component of needle planning algorithms for computing brachytherapy needle arrangements.

The needle planning problem can be posed using the following statement: find a set of skew-line segments that originate at some allowable entry zone for needles, that do not puncture any avoidance volumes, and that spatially cover the target volume. For the last point, spatial coverage means that every point in the target volume is nearby to at least one needle. Figure 1 shows a target volume, avoidance volume, and entry zone, which in anatomical terms represent the prostate, penile bulb, and perineum, respectively. NPIP solves this problem by generating a large set of candidate needles that originate at the entry zone, intersect the target volume, and do not intersect the avoidance volume, then selects a subset of candidate needles for insertion that is minimal and provide spatial coverage of the target.

Currently, candidate needles are generated by random
sampling, and needles that intersect the avoidance volumes are removed from this set. Consequently, it is possible to have non-trivial “voids” in the target volume that are not nearby to any candidate needle, and by extension to any selected needle, which can result in inadequate dose to the target and diminish treatment effectiveness. These voids can be a result of inadequate sampling or because the volume is “occluded”. That is, it cannot be reached by any straight line segment originating in the entry zone that does not also intersect the avoidance volume. Figure [1] shows an example occluded volume. An algorithm for finding occluded volumes would prevent needle planning algorithms like NPIP from generating voids that are not actually in occluded volumes, and allow these algorithms to handle occluded volume in a controlled way; for example, selecting more needles that are near the occluded volume to provide better dose coverage.

This study develops an exact algorithm for finding an occluded volume based on shadow volume calculations from the visibility literature. Although this study only considers a system with only a single target, avoidance volume, and entry zone, our algorithm is extensible to multiple targets, avoidance volumes, and entry zones. Specifically, our contributions are the following:

(a) an exact algorithm for finding an occluded volume that exploits the geometric structure and constraints of prostate brachytherapy,

(b) a check for the existence of an occluded volume that is polynomial time in the number of vertices describing the relevant volumes.

We use our algorithm to find the occluded volume, or show that none exists, for data sets from brachytherapy patients treated at the UCSF clinic. Given the uncertainty in defining anatomical structures, we also use our algorithm to perform a sensitivity analysis on systematic perturbations of the avoidance volume and entry zone.

II. BACKGROUND AND RELATED WORK

The problem of finding occlusions has been well-studied in computer graphics and computational geometry. Scherzer et al. [5] provide a survey in shadow computations. These are often performed at a pixel level exploiting parallel computing for handling real-time rendering of large discrete models. [6] provides efficient algorithms for such calculations. Recent work has also focused on sub-pixel shadow mapping for handling issues like jagged shadows and aliasing and has been discussed in [7], [8]. Research in automation has looked at similar problems regarding polyhedral assembly [9].

This study examines the problem of checking existence of occluded volume in a polyhedral complex. Our algorithm exploits assumptions about the geometry of prostate brachytherapy, which we use to simplify our problem statement compared to a general occlusion problem statement. We also develop a linear program that is feasible if and only if an occluded volume exists. Thus the existence of the occluded volume can be checked in polynomial time in the total number of vertices (i.e., of the target volume, avoidance volume, and entry zone) without having to perform expensive polyhedron intersection calculations.

Our goal is to introduce automation into the brachytherapy treatment process. We have worked on several aspects of the problem: treatment planning [10], [11], needle configuration planning [2], [12], robotic needle placement [3], [13], [14], and recently the use of custom guides for brachytherapy needle placement [4], [15].

In prostate brachytherapy, an arrangement of hollow needles is inserted into the prostate through the perineum, the patch of skin between the testicles and anus. Radiation dose is delivered to the prostate by sequentially threading a radioactive source through each needle. The dose distribution is controlled by halting the source at pre-specified locations along each needle for some dwell time. Most clinicians insert needles using a rigid template with parallel holes as a needle guide [16]. However, this template restricts the possible insertion locations and directions, which can make puncturing obstructions such as penile bulb unavoidable. Puncturing healthy tissues results in trauma related side-effects such as tissue swelling; urinary infections & incontinence; and impotence [18], part 7], [19], [20]. A freehand approach for needle insertion based on trans-rectal ultrasound guidance was developed [17]. This technique gives the physician some flexibility to avoid puncturing healthy tissue, but it requires experience to master.

Siauw et al. [2] recently proposed a novel algorithm, NPIP, which computes patient-specific needle arrangements based on skew line segments. Since these needles can be inserted at a continuum of angles, it is non-intuitive for a human operator to implant the configuration. However, such a skew line needle arrangement can be implanted using an automated needle insertion robot as in Garg et al. [3], [21] or using customized templates [4]. The development of needle planning is shown in Figure 2.

NPIP has three main steps – candidate needle generation, needle selection, and dose planning. The candidate needle set is generated by random sampling line segments that originate from the entry zone are inside a projection of the prostate.
The needle selection step finds a candidate needle subset such that every point in the target is within some user-defined distance from a needle in the chosen set. The heuristic helps ensure that the target can be covered with adequate dose during dose planning. Dose planning is done using Inverse Planning by Integer Program (IPIP) [11], which maximizes dose coverage of the target using the chosen needles within dose limits to healthy tissue.

Sometimes there are points in the target volume that cannot be covered by any needle in the candidate needle set (i.e. they are not within the user-specified distance from any candidate needle). Currently, these points are ignored in the needle selection step. Although ignoring these points does not impact the final solution when the number of ignored points is small, it is desirable to generate a candidate needle set that can cover point that can be covered given the geometric setup, and prove that the uncovered points cannot be covered. Such a guarantee, which can be provided by the algorithm we present in this study, could provide bounds on the quality of treatment, and allow the system to adjust its solution strategy to accommodate the occluded, or unreachable, volume. For example, the “importance” of needles that are near the occluded volume could be increased to encourage their selection. Thus, the resulting solution would have a concentrate of needles near the occluded volume, which would allow for dose coverage, even though the volume did not have spatial coverage of needles.

### III. Problem Statement

**Notation:** Given a target volume $T$, an avoidance volume $A$, and an entry zone $E$, we are interested in finding an analytical description of an “occluded volume” $O$, contained within the target volume $T$ or show that no such “occluded volume” $O$ exists. The latter case implies that every point in the target volume $T$ can be reached by a line segment from some point in the entry zone $E$ without intersecting the avoidance volume $A$.

The needle selection step finds a candidate needle subset such that every point in the target is within some user-defined distance from a needle in the chosen set. The heuristic helps ensure that the target can be covered with adequate dose during dose planning. Dose planning is done using Inverse Planning by Integer Program (IPIP) [11], which maximizes dose coverage of the target using the chosen needles within dose limits to healthy tissue.

Sometimes there are points in the target volume that cannot be covered by any needle in the candidate needle set (i.e. they are not within the user-specified distance from any candidate needle). Currently, these points are ignored in the needle selection step. Although ignoring these points does not impact the final solution when the number of ignored points is small, it is desirable to generate a candidate needle set that can cover point that can be covered given the geometric setup, and prove that the uncovered points cannot be covered. Such a guarantee, which can be provided by the algorithm we present in this study, could provide bounds on the quality of treatment, and allow the system to adjust its solution strategy to accommodate the occluded, or unreachable, volume. For example, the “importance” of needles that are near the occluded volume could be increased to encourage their selection. Thus, the resulting solution would have a concentrate of needles near the occluded volume, which would allow for dose coverage, even though the volume did not have spatial coverage of needles.

**Definition:** A truncated occlusion cone $C_e$ is the polyhedron which characterizes the occluded volume generated by a convex set of vertices $A$ as viewed from a point $e \notin Conv(A)$. As shown in Figure 3, $C_e$ consists of the faces of $A$ visible from $e$ and all points behind them generated as a conic hull of rays corresponding to visible extreme points. Formally,

$$C_e = \left\{ x \in \mathbb{R}^n : x = e + \sum_{j \in J} \lambda_j (A_j - e), \quad \sum_{j \in J} \lambda_j \geq 1, \quad \lambda_j \geq 0, \forall j \in J \right\}$$

**Assumptions:** We have assumed that the objects in the environment can be represented as finite polyhedra, and hence are convex. In case of brachytherapy, the organs are contoured by a physician and polyhedral representation results in the convex hull of the contour. We work with a planar region $E$, represented by its extreme points. Furthermore, there is no intersection between either of the objects: $T$, $A$ and $E$.

In case of a non-planar specification of $E$ we can find a suitable projection on a plane. In case of non-convex objects, we can represent them as a disjoint union of convex sets. The algorithm outputs an occluded volume for each convex subset, and the union of these results in final occluded volume. We note that in this case the final occlusion region may not be necessarily convex.
IV. ALGORITHM

The proposed algorithm exploits the observation that every point \( p \) in the intersection of truncated occlusion cones \( C_i \) generated from vertices \( E_i \) of a convex closed region \( \mathcal{E} \) also lies in the truncated occlusion cone \( C_e \) generated from any other point \( e \) in region \( \mathcal{E} \).

Stating the above formally:

\[
\forall p \in \bigcap_{i \in I} C_{E_i}, \quad \exists \lambda \in \mathbb{R}^A : \sum_{j \in J} \lambda_j \geq 1; \quad \lambda \geq 0
\]

such that:

\[
p = e + \sum_{j \in J} \lambda_j (A_j - e) \quad \text{i.e.} \quad p \in C_e,
\]

where

\[
e = \sum_{i \in I} \mu_i E_i, \quad \sum_{i \in I} \mu_i = 1, \quad \mu_i \geq 0, \quad \forall i \in I
\]

(2)

This entails that any point in \( T \) occluded from \( E_i, \forall i \in I \) is also occluded from any point in \( \mathcal{E} \). Every point \( p \notin \bigcap C_i \) is classified as visible, since \( p \in C_i \) for at least one \( i \in I \). Also, every point \( p \in C_e \) is either visible from at least one \( E_i \), i.e. \( p \notin C_i \), or lies in the occluded volume \( O \), if it exists, i.e. \( p \notin \bigcap C_i \).

An intuitive explanation for this observation is if a point \( p \in \bigcap C_i \), then none of the \( E_i \)'s can see \( p \). Moreover, by reversibility of visibility, \( p \) can't see any of the \( E_i \)'s either. Since \( \mathcal{E} \) is convex, hence by extension \( p \) should not be able to see any other point in \( \mathcal{E} \). Moving the viewing perspective to any point \( e \in \mathcal{E} \), and by similar argument as above, any \( e \in \mathcal{E} \) can't see \( p \) either.

This observation significantly improves the computational effort in calculation of the occluded volume, since we only need to generate truncated occlusion cones on the finitely many vertices of the convex region \( E \), instead of every point in \( E \), or a discretization thereof.

Hereafter, we build a linear system of equations to check for existence of an occluded region \( O \). The system [3] is feasible if \( O \) is non-empty and infeasible otherwise. If the system of equations return feasibility, we calculate the polyhedral representation of \( O \) using an iterative method for intersecting polyhedrons.

A. Check for Existence of Occlusion Volume \( O \)

Assume \( O \) is non-empty, and let a point \( x \in O \). Then by definition, \( x \) must have the following two properties:

(1) It must be a convex combination of the vertices of \( T \) (since \( O \subseteq T \)).

(2) The line segment between \( x \) and some point \( e \in \mathcal{E} \) must have at least one point that is a linear combination of the vertices of \( A \).

\[
x = \sum_{k \in K} \mu_k T_k,
\]

\[
\sum_{k \in K} \mu_k = 1, \quad \mu_i \geq 0, \quad \forall i \in I,
\]

which is simply the definition of convex combination representing the first condition.

While the second condition is represented by \( x \in C_e \). In other words, the conic hull of \( A \) from \( e \) is the set of rays originating at \( e \) that have at least one point in \( A \), i.e., at least one point that is a linear combination of the vertices of \( A \). So by definition, \( x \) must be in the intersection of \( C_e, \forall e \in \mathcal{E} \).

\[
x \in \bigcap_{e \in \mathcal{E}} C_e.
\]

To simplify our representation of this property of \( x \), which requires an intersection of an infinite number of conic hulls, it is sufficient to find the intersection of the conic hulls of \( A \) around \( E_i, i \in |E| \), the vertices of \( \mathcal{E} \). That is,

\[
\bigcap_{e \in \mathcal{E}} C_e = \bigcap_{i \in I} C_{E_i}
\]

We can then represent the second property of \( x \) using

\[
x = E_i + \sum_{j \in J} \lambda_{ij} (A_j - E_i), \quad \forall i \in I
\]

\[
\sum_{j \in J} \lambda_{ij} \geq 1, \quad \forall i \in I, \quad \lambda \geq 0,
\]

which states that \( x \) must be in the conic hull of \( A \) originating at \( E_i, i \in I \). We note that the condition: \( \sum_{j \in J} \lambda_{ij} \geq 1, \forall i \in I \), enforces that only the points situated beyond the visible boundary of the avoidance region \( A \) are included.

Put together, we get our linear system, (LS).

\[
\text{(LS)} \quad x = E_i + \sum_{j \in J} \lambda_{ij} (A_j - E_i), \quad \forall i \in I
\]

\[
x = \sum_{k \in K} \mu_k T_k,
\]

\[
\sum_{k \in K} \mu_k = 1, \quad \mu_i \geq 0
\]

\[
\sum_{j \in J} \lambda_{ij} \geq 1, \quad \forall i \in I, \quad \lambda_{ij} \geq 0, \quad \forall i \in I, \quad \forall j \in J.
\]

(3)

By construction, any \( x \) value that satisfies (LS) cannot be connected to a point in \( \mathcal{E} \) by a line segment that does not intersect \( A \). Therefore, the feasible region of \( x \) in (LS) is exactly \( O \), the occluded volume. Consequently, if (LS) is infeasible, then \( O \) is empty and the entire target volume can be reached by at least one line segment originating in the entry zone that does not intersect the avoidance volume. If (LS) is feasible, then \( O \) is not empty, and it is worth noting that since the feasible region is made up from a set of linear constraints and is bounded by \( T \), that \( O \) is a polytope when it is not empty.

B. Calculation of Occlusion Volume \( O \)

To obtain the polytope \( O \), we employ the following algorithmic outline:

Solve the system \( (LS) \) as LP with zero cost

if LP is infeasible then \( \triangleright \) no occluded volume exists

else if LP is feasible then \( \triangleright \) exists occluded volume

for \( i \in I \) do

compute the smallest cone \( C_{E_i} \) pointed at \( E_i \) covering \( A_j \), \( j \in J \)

end for

compute the intersection \( C \) of cones \( C_{E_i}, \forall i \in I \)
compute the Occluded Volume $O$ as the intersection between $C$ and target $T$.

**end if**

Polypotes can be described using inequalities (H-polypotes) or vertices (V-polypotes). H-polypotes can be converted to V-polypotes using vertex enumeration and vice-versa by facet enumeration. In our case we have input as V-polypotes while output as H-polypote for a complete representation of $O$. A preliminary approach is start by converting the input to H-representation. Then the intersection is a redundancy removal problem in the union of two inequality systems. To get vertices of $O$, we solve a vertex enumeration.

**C. Complexity Analysis**

The linear system of equations for checking existence of an occluded volume can be solved as an LP. LP have known polynomial time complexity [22]. Assuming $A$, $T$ and $E$ have $m_1$, $m_2$ and $m_3$ points respectively and dimension of space being $n$. Furthermore, also assuming non-degeneracy we have: $n \leq m_1 + m_2 + m_3$. Then, the system [3] has $(n+m_1+m_2+m_3)$ variables and $(n(m_2+1)+m_3+1)$ constraints apart from the non-negativity constraints.

Furthermore, in case there exists an occluded volume or the linear system [3] returns feasible solution, we calculate truncated occlusion cones $C_{E_i}, \forall i \in I$. Thereafter, a sequence of polyhedral intersections are performed to obtain $C := \bigcap C_{E_i}$. Polyhedral intersection in general is shown to be NP-Hard [23], however, using the above approach, solving for redundancy in union of $k$ H-polypotes is an LP. An intersection of two such occlusion cones can be performed in polynomial time in [24] for low dimension. Every occlusion cone $C_e$ has $O(m_2)$ extreme rays. We perform $m_3$ such intersection operations for calculating $C := \bigcap C_{E_i}$, and thereafter one more intersection with target volume $T$ to get obtain $O$. Hence the complexity is $O(m_2m_3)$.

**V. EXPERIMENTS AND RESULTS**

**A. Preprocessing Clinical Dataset**

We tested our algorithm on 18 anonymized anatomy cases taken from patients previously treated at UCSF. This data set contained surface points on the prostate and the penile bulb, which were termed as the target volume $T$ and avoidance volume $A$, respectively. The prostate volumes ranged from 27 to 97 cm$^3$ and the penile bulb volumes ranged from 1 to 11 cm$^3$.

A specification of the entry zone did not exist in the data set because segmenting an entry zone is not a standard procedure. The perineum in human anatomy is also ∼4 cm below the penile bulb. This is a reasonable anatomical proxy for the perineum since the distance between the penile bulb and the perineum in human anatomy is also ∼2 cm. This is a conservative estimate of the possible entry zone; however, it ensures that we restrict the entry zone to an area used by the physician. We note that the entry zone to allow for skew-line needles could be larger than this, which would reduce occlusion. The entry zone area ranged from 7 to 13 cm$^2$.

**B. Occluded Volume Analysis**

We implemented our algorithm in Matlab. We used the Matlab interface for Multi-Parametric Toolbox 3 (MPT) [23] to calculate extreme points of a convex bounded polyhedra and to perform polyhedral intersection operation. MPT toolbox implements polyhedral intersection queries in low dimension using the approach described in section IV-B. The algorithm was run on a computer with OS/X 10.9.2m 2.7 GHz Intel core i7, and 16 GB memory.

Table I lists the size of occluded volumes for the different cases in the dataset. For all cases, we checked for the existence of an occluded volume in the prostate where needles cannot reach without puncturing the penile bulb. We found that 11 out of 18 patients had a non-empty occluded volume. Among the patients with occlusion, the size of the occluded volume ranged from 0.06 cm$^3$ to 2.4 cm$^3$ or 0.01% to 4.3% of the respective target volume. The running time ranged from 4 s to 9 s. It is worth noting that time on the order of seconds is inconsequential to the overall brachytherapy workflow.

**C. Sensitivity Analysis**

The size of the penile bulb has substantial uncertainty in its definition owing to difficulty in its identification on a CT scan. We used our algorithm to compute the occluded volume in each patient’s target volume for various dilations of the nominal penile bulb. The dilations were computed by expanding the vertices of the penile bulb about its centroid by a dilation factor ($\alpha$) that ranged from 0.75 to 1.25 in increments of 0.05, where $\alpha = 1$ results in no change (i.e. its original size). For each iteration, we recorded the size of

</tbody>
</table>
the occluded volume, the volume of the dilated bulb, and the running time of the algorithm.

Likewise, entry zone specification used in the dataset is a conservative estimate. Dilation of the entry zone is prone to introduction (or removal) of occlusion. We have performed calculations of occluded volumes for various dilations of the entry zone about its centroid by a dilation factor (\(\alpha\)) in \([0.5, 1.5]\) in increments of 0.05.

Figures 4a and 4b show variation in existence and size of occluded volume as a % of target volume for various values of dilation factor \(\alpha\) in case of penile bulb and entry zone, respectively. The error bars for each \(\alpha\) value represent the measure of the standard deviation for the whole data set. An error bar corresponding to an Occlusion Volume < 0% implies no occlusion exists. Figure 5a shows change in occluded volume with avoidance volume (penile bulb) dilation in one particular anatomical case. Similarly, Figure 5b shows the change in occluded volume with entry zone dilation for another case in the data set.

**VI. DISCUSSION AND FUTURE WORK**

The occluded volume in the target, where needles starting in the entry region cannot reach without puncturing the avoidance volume (penile bulb), if it exists, is found for all 18 cases in the data set. Computational results listed in Table I reveal that \(\sim 60\%\) (11 out of 18) of cases in the data set have non-zero occluded volume. Owing to the variance in location and size of the organs and the entry zone, the results ranged from no occluded volume to (4.3%) of the prostate being occluded.

In practice, an occluded volume inside the target volume could lead to voids in needle coverage, which results in areas that are difficult to cover with adequate dose and thus make the overall treatment of the patient less effective.

Furthermore, the effect of dilation on the avoidance volume and entry zone to occluded volume emphasizes the importance the proposed approach. As noted earlier, identification of true boundaries of the penile bulb may be difficult, and hence a conservative estimate may be made. We note from Figure 4a that the occluded volume is fairly sensitive to dilation of avoidance volume. Conservative errors of 5% in specification of margins of avoidance volume may result in > 5% of the target volume being occluded in some cases.

Moreover, the entry zone is not always precisely defined. A similar analysis shows that the occluded volume is relatively less sensitive to entry zone perturbation than to avoidance volume perturbation. As noted in Figure 4b, a 10% contraction in entry zone results in \(\sim 5\%\) occlusion in target volume. While on the other hand, at 40% expansion of entry zone, all cases result in 0 occluded volume.

Figures 5a and 5b provide qualitative review of occlusion events and resulting occluded volumes for a particular case highlighting the rapid growth of occluded volume with dilation of avoidance volume and entry zone respectively.

The errors in estimating avoidance volume and entry zone may not always be isotropic as the centroidal dilation in the sensitivity analysis. However we note that occluded volume is often resultant of obstruction from a small subset of neighboring faces. However, prior knowledge of this obstructing boundary is not available to the user, necessitating a check in all directions.

Moreover, in case of non-zero occluded volume, we could perform a similar perturbation in the entry region vertices cyclically instead of isotropic dilation. This would result in identification of directions, expansion in which would result in elimination of occlusion.

**Future Work:** In addition to checking feasibility of a brachytherapy procedure without puncturing healthy organs, the output of the algorithm can be used to improve treatment planning. In case the target is not completely visible, we can calculate the extreme points of the entry zone which can reach the boundary of the occluded volume in target. Needles starting from these points can be adaptively reweighted for
higher “importance” in the needle subset selection optimization of the NPIP algorithm [2].

Limitations: The complexity of the algorithm is proportional to the number of vertex points in the convex hull of the polyhedra. A high fidelity representation would thus result in slow computations. Furthermore, for time critical applications, faster implementation of polyhedral intersection operation with use of parallel computing may be explored.

Extensions: The framework can be generalized to have more than one avoidance volumes, for instance pubic arch in case of prostate brachytherapy. In case of a non-convex avoidance volume, a preprocessing step would section it into disjoint convex subsets. The procedure can then be used in parallel for each subset, and performing a union operation in the end.

Moreover, the algorithm is also applicable to other applications with reachability calculations: such as visual inspection, robotic spray painting, and other clinical procedures such as biopsy. Kidney biopsy is a one such problem where the physician is interested in reaching a particular region inside kidney without puncturing healthy organs.

VII. CONCLUSION

This paper considers the problem of exact reachability analysis for checking existence of occluded volume in a polyhedral target in presence of a polyhedral avoidance volume not reachable from a polyhedral entry region. The proposed algorithm performs the check in polynomial time and if it exists returns the polyhedral representation of the occluded volume. This study forms a basis for identification of candidate needle set generation and needle subset selection for treatment radiotherapy treatment planning in brachytherapy. We have shown computational results on actual anatomical cases of prostate cancer, and quantified the occluded volume in each case. We have found that 11 out of 18 cases have non-empty occluded volume ranging from 0.01% to 4.3% of target volume. Such occlusions can lead voids in radiation coverage, thus reducing the effectiveness of overall treatment. Furthermore, we have conducted a sensitivity analysis to study change in occluded volume with dilation of the the avoidance volume and the entry zone.
